Abstract

The topic of intermediate languages for optimizing and parallelizing compilers has received much attention lately. In this paper, we argue that any good representation of a program must have two crucial properties: first, it must be a data structure that can be rapidly traversed to determine dependence information, and second this representation must be a program in its own right, with a parallel, local model of execution. In this paper, we illustrate the importance of these points by examining algorithms for a standard optimization — global constant propagation. We discuss the problems in working with current representations. Then, we propose a novel representation called the *dependence flow graph* which has each of the properties mentioned above. We show that this representation leads to a simple algorithm, based on abstract interpretation, for solving the constant propagation problem. Our algorithm is simpler than, and as efficient as, the best known algorithms for this problem. An interesting feature of our representation is that it naturally incorporates the best aspects of many other representations, including continuation-passing style, data and program dependence graphs, static single assignment form and dataflow program graphs.

1 Introduction

The growing complexity of optimizing and parallelizing compilers has re-focused the attention of the programming languages community on the design of *intermediate program representations*. Some well-known representations are: control flow graphs [2], def-use chains [2], data dependence graphs [14], program dependence graphs and webs [12, 6], program representation graphs [8], static single assignment form [10], continuation-passing style [19], and program graphs [1]. The choice of program representation has a profound effect on the design, asymptotic complexity, and implementation of optimizing and parallelizing transformations. As an analogy, consider Hindu numerals[3], which are more convenient than Roman numerals for performing arithmetic operations, while representing the same information. In this paper, we argue that a good intermediate representation should have the following properties:

- It should be executable. That is, it should be a language with a well-defined, compositional operational semantics. This allows abstract interpretation to be employed when designing algorithms, which facilitates systematic algorithm development and proof of correctness [9].
- It should be possible to view the representation as a data structure that can be traversed efficiently for data dependence information, as required by many compiler transformations [14].
- Loops should be represented explicitly. Some representations replace loops with tail-recursive procedures [3, 11]. In our experience, this transformation is not desirable since many important loop transformations, such as loop interchange, have no natural analog in the context of tail-recursive procedures.
- The storage model should include an updatable, imperative store. The operational semantics of an imperative language is phrased naturally in terms of an updatable store. While it is possible to treat the store functionally (as is done in denotational semantics), such treatments are quite clumsy in dealing with data structures, especially arrays [4].
- The representation should be compact. A new program representation whose size is asymptotically bigger than that of well-accepted representations (such as def-use chains) is unlikely to gain acceptance.

In this paper, we illustrate the importance of these issues by examining a particular optimization — global constant propagation. This optimization is performed by all optimizing compilers and is representative of "scalar" optimizations such as partial redundancy elimination and strength reduction. We discuss the drawbacks of the representations cited

[3]Because of an unfortunate instance of aliasing, these are known as Arabic numerals in the West.

above, and demonstrate how a representation that meets our criteria leads to a simple, elegant algorithm based on abstract interpretation. This algorithm is as efficient as the best algorithms that use the other forms, and has an elegant proof of correctness. Our representation, called the *dependence flow graph*, is based on a generalization of the dataflow model of computation, called *dependence-driven execution*. Interestingly enough, many features of previously proposed intermediate representations arise naturally in the context of dependence flow graphs.

In Section 2, we illustrate the drawbacks of previously proposed representations by describing how constant propagation is performed on these representations. In Section 3, we present dependence flow graphs along with a formal, Plotkin-style operational semantics. In Section 4, we present our algorithm for constant propagation on dependence flow graphs, and we indicate a proof of correctness. Finally, in Section 5 we discuss ongoing work.

2 Constant Propagation

In this section, we examine the problem of global constant propagation, a standard analysis performed by optimizing compilers. We define a particularly ambitious class of constants, the *possible-paths constants*, which is discovered by an algorithm due to Wegman and Zadeck [20]. We then consider a number of intermediate forms most commonly used for optimization in imperative language compilers. Finally, we show how previous constant propagation algorithms have been affected by the shortcomings of these underlying representations.

2.1 Problem Description

A *definition* of a variable x is a statement that assigns (or may assign) to x. A *use* of x is an occurrence of x in a statement that reads (or may read) the value of x. We say that a definition of x *reaches* a use of x if execution of the definition may be followed by execution of the use without intervening execution of any other definition of x. As is standard, this definition assumes that conditional branches may go either way [2].

If the right hand side of a definition of x is a constant c, we can sometimes substitute c for a use of x without changing the meaning of the program. For example, in Figure 1(a), the first use of z can be replaced by 1 and the second by 2. This is a simple example of *constant propagation*. If all of the variables on the right hand side of a definition are replaced by constants, then we can evaluate the expression and replace it by a constant.

```
if (p) then
    { z := 1; x := z+2 }
    else
    { z := 2; x := z+1 }
y := x
```

(a) all-paths

```
p := true
if (p) then
    { x := 1 }
    else
    { x := 2 }
y := x
```

(b) possible-paths

Figure 1: Examples of runtime constants

Recursively, this opens up fresh opportunities for constant propagation. For example, in Figure 1(a), the right hand sides of the two definitions of x can be simplified to the constant 3. The use of x in the last statement is reached by *two* definitions of x. However, since the right hand sides of both definitions are the same constant, we can replace the use of x by 3 without changing the meaning of the program. This motivates the following definition.

An *all-paths constant* is either:

- a constant expression c, or
- an expression e over some set of variables $\{v_1, v_2, \ldots v_n\}$ such that for each v_i, the right hand side of every definition of v_i that reaches e is an all-paths constant c_i.

The class of all-paths constants takes no account of constants in conditionals. However, if the predicate of a conditional can be determined to be constant, then we can ignore the effect of definitions on the side that is never executed. If we modify the definition of all-paths constants to exclude such definitions, the result is the class of *possible-paths constants* [20]. In Figure 1(b), the use of x in the last statement is a possible-paths constant with value 1. Note that this use is not an all-paths constant.

A variety of algorithms for constant propagation have been proposed in the literature [2, 13, 18, 20]. Some of these algorithms are more powerful than others — for example, only the algorithm of Wegman and Zadeck [20] finds possible-paths constants in a single pass. Repeated application of the less powerful algorithms, combined with dead code elimination, will find all possible-paths constants. However, repeated rounds of program transformation and analysis are expensive, and so we seek to discover as many constants as possible in a single pass through the program. As we will see, the choice of program representation plays a critical role in this task.

It is standard to express constant propagation algorithms in the framework due to Kildall [13]. We define a lattice *Lat* shown in Figure 2, consisting of all the constant

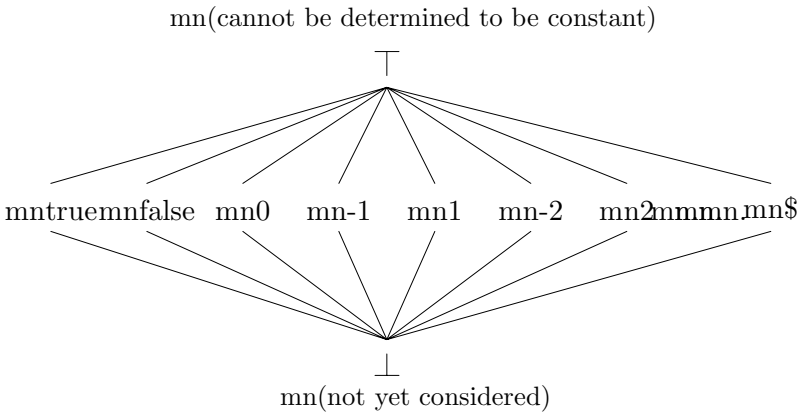

Figure 2: *Lat* — Lattice for constant propagation

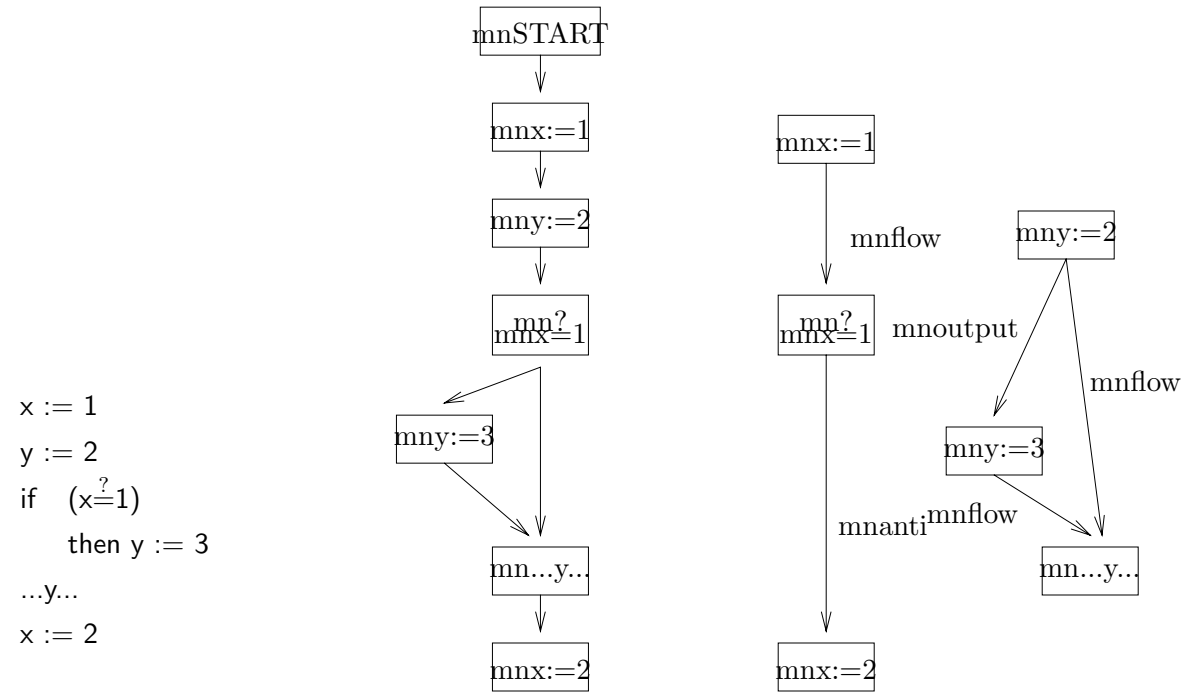
values and two distinguished values $\top$ and $\bot$. The special constant `$` is used only in dependence flow graphs, and plays no part in the algorithms described in this section. Uses of variables are assigned values from *Lat* during constant propagation. Initially, every use of every variable is mapped to $\bot$, meaning that we have no information yet about the values that it is assigned at runtime. A use is mapped to $\top$ when the algorithm cannot determine that the use is a constant (*e.g.* if the use is reached by two definitions whose right hand sides are 3 and 4.)[4] At the end of constant propagation, the interpretation of the lattice value assigned to a use of a variable `x` is as follows:

- $\bot$: This use was never examined during constant propagation; it is dead code.
- c: This use of `x` has the value c in all executions.
- $\top$: This use of `x` may have different values in different executions.

To permit evaluation of right hand sides of definitions in the abstract interpretation, it is convenient to extend the usual arithmetic and boolean operators so that they can take

[4]Note that the sense of $\top$ and $\bot$ in the lattice are reversed with respect to the lattice used by previous researchers [13, 18, 20]. These researchers viewed constant propagation as an all-paths data flow problem; such problems are traditionally formulated so that the desired solution is the *greatest* fixed point of a set of equations. In our framework, we will use abstract interpretation to find constants, and it is more convenient to formulate the desired solution as the *least* fixed point of a set of equations.



(a) Source Program (b) Control Flow Graph (c) Data Dependence Graph

Figure 3: A Small Program and its Representations

$\perp$ and $\top$ as arguments. For example, the operator v1 + v2 is interpreted as follows:

$$Plus(v_1, v_2) = \begin{cases} \top & \text{if } v_1 = \top \text{ or } v_2 = \top \\ c_1 + c_2 & \text{if } v_1 = c_1 \text{ and } v_2 = c_2 \\ \perp & \text{otherwise} \end{cases}$$

2.2 Control Flow Graphs

Figure 3(b) shows the *control flow graph* [2] for a small imperative program. Nodes are either assignment statements or conditional expressions that affect flow of control, and edges represent possible transfer of control between nodes. An assignment node has a single successor while a conditional node has two successors representing the possible branching of control. In our figures, we follow the convention that the *true* branch of a conditional is always left-most. Algorithms for constructing the control flow graph representation of a program are well-known [2]. Control flow graphs have a simple sequential semantics based on transforming a global imperative store.

A simple algorithm based on abstract interpretation finds possible-paths constants in the control flow graph. At each node, we maintain a vector of values from *Lat*. These vectors have an entry for each variable, and intuitively, they summarize the possible values

of variables before the statement is executed. Initially, every entry at every node is set to $\perp$ except at the START node where the entries are set to $\top$. These values are updated monotonically (in the lattice-theoretic sense) as the algorithm proceeds.

The algorithm maintains a worklist of nodes to be processed; initially, this worklist contains all of the nodes immediately following the START node. Nodes are dequeued from the worklist and processed as follows. Let N be a node from the worklist, and let N_{in} be the vector at the input of N.

- If the node is an assignment statement, (say x := e), then the expression e is evaluated, using the values of variables in N_{in}, and a new vector N_{out} is created that is identical to N_{in} except at x where it has the value just computed for e. The vector N_{out} must be propagated to the successor node S of the assignment statement. Let S_{in} be the vector at the successor node. This vector is updated to the join of its value and N_{out}.[5] If this changes the value of S_{in}, then S is added to the worklist.

- If the node is a conditional branch, then the predicate is evaluated. If the value of the predicate is $\top$, then the vector N_{in} is propagated to both successors of the conditional branch. If the value of the predicate is *true* or *false*, then N_{in} is propagated only along the corresponding side of the conditional branch. If the value of the input vector changes at a successor, then the successor is added to the worklist.

We leave it to the reader to verify that this algorithm will find all of the constants in Figure 1. Unfortunately, the asymptotic complexity of this algorithm is poor. If we let V be the number of program variables and N the number of statements, then the algorithm requires $O(NV)$ space and $O(NV^2)$ time. Although the abstract interpretation algorithm on control flow graphs is simple, it is not used in practice because of its high cost.

The inefficiency arises because lattice values must be propagated along control flow paths from definitions of variables to their uses. What is needed is a "sparse" representation that links definitions to the uses they reach, so that we can propagate the values of individual variables to places where they are needed, rather than propagating the values of all variables to all program locations. Def-use chains and their generalization, data dependence graphs, provide such a representation.

2.3 Data Dependence Graphs

Def-use chains are graphs that have the same nodes as control flow graphs, but the edges connect each definition of a variable to all uses reached by that definition. For compilers

[5] We cannot simply store N_{out} at S_{in} because S may have other predecessors. If a node has two predecessors, $x := 2$ and $x := 3$, then the entry for x at its input should be $\top$.

that perform wholesale reorganization of programs, a generalization of def-use chains called the *data dependence graph* [14] is commonly used. The data dependence graph for our example is shown in Figure 3(c). Edges in the graph represent dependencies that are classified as *flow* (def-use), *anti* (use-def), or *output* (def-def) dependences.

Note that the data dependence graph is not an executable representation and does not incorporate information about flow of control. For example, in Figure 3(c), execution of the definition $\mathsf{y} := \mathsf{3}$ is not related to the predicate $\mathsf{x} \stackrel{?}{=} \mathsf{1}$ in any way. Negating the predicate will change the value of y that is read, but this does not change the dependence edges that sequence operations on y.

The constant propagation algorithm based on def-use chains is similar to the one described earlier for control flow graphs, except that we propagate lattice values from definitions to uses along def-use edges, rather than along control flow paths. At each node, we keep a vector containing values only for those variables that are used by the node. A worklist is kept of nodes to be processed. Initially, every definition whose right hand side is a constant c is placed on this worklist.

To process a definition of the form $\mathsf{x} := \mathsf{e}$, the expression e is evaluated, and its value is propagated along def-use edges originating at this node to nodes that use x. Conditional nodes do not need any processing, since there are no def-use chains originating at these nodes. The complexity of this algorithm is linear in the size of the def-use chains of the program.

If we let $E \leq 2N$ be the number of edges in the control flow graph, then a naive representation of def-use chains can be $O(E^2V)$ in size. However, Reif and Lewis have shown that a factored form of def-use chains can be represented in size $O(EV)$ [18]. This yields an algorithm which is a factor of V faster than the one which uses the control flow graph.

Although this algorithm will find all-paths constants as in Figure 1(a), it will not find possible-paths constants as in Figure 1(b). In relying on data dependence information to direct the flow of values, we have lost important connections between data dependence and flow of control. In our control flow algorithm, values were propagated down only one side of a conditional with a constant predicate. This was possible because the control flow path from the definition to the use passed through the conditional. Def-use edges do not flow through conditionals, but reach directly from definitions to uses. Thus, our new algorithm does not find all possible-paths constants, and we conclude that def-use information needs to be augmented with control flow information in some way.

2.4 Control Flow Graphs with Data Dependence Graphs

Most optimizing compilers generate a control flow graph as a first step towards computing the data dependence graph. This suggests the development of "hybrid" algorithms that use both data structures. The constant propagation algorithm described next is adapted from that of Wegman and Zadeck [20].

To find possible-paths constants while still obtaining the efficiency of def-use chains, Wegman and Zadeck refer back to the control flow graph. To keep propagation of values from bypassing conditionals, a boolean *executable* flag is added to each statement, and is initially set to *false*, except for START. The executable flag indicates that the statement may be executed, *i.e.,*that it has not been determined to be dead.

Lattice values flow along def-use chains as before; in addition, information about which nodes may execute flows through the control flow graph. These two flows are not independent since intermediate results of constant propagation may be used to determine that one side of a conditional is never executed. Conversely, a definition does not participate in constant propagation until it is determined that it may be executed. Two worklists keep track of these two flows: the *flow* worklist and the *def* worklist.

The flow worklist is used to propagate the executable flag through the control flow graph. If a non-conditional node N may be executed, then its successors may be executed. Once the predicate of a conditional has been assigned a lattice value, the executable flag can be propagated down one or both sides as appropriate.

The def worklist is used to propagate lattice values along def-use edges as in the previous algorithm. Nodes are placed on a worklist only if their executable flag is *true*; conditionals are placed on the flow worklist and definitions are placed on the def worklist. Initially, the flow worklist contains only START and the def worklist is empty.

Although this algorithm finds the possible-paths constants in Figure 1, it fails to discover the one-sided possible-paths constant in Figure 4(a) since the assignment $\mathsf{x} := 2$ reaches the use of x and is not dead. Wegman and Zadeck suggest transforming every one-sided conditional by inserting a dummy assignment of the form $\mathsf{x} := \mathsf{x}$ on the else branch. In the transformed program, as in Figure 4(b), only one value is propagated through the conditional if the predicate is constant. When performed on the transformed program, the Wegman-Zadeck algorithm does find the possible-paths constants.

The problem of maintaining two data structures to represent the program's execution semantics and its dependencies is addressed in part by the *program dependence graph*. This graph consists of the data dependence graph augmented with *control dependence* arcs. A more elegant constant propagation algorithm based on the one described in this section can be developed using the program dependence graph. However, program dependence

```
x := 2
p := true
if (p) then { x := 1 }
y := x
```

(a) one-sided

```
x := 2
p := true
if (p) then { x := 1 }
       else { x := x }
y := x
```

(b) dummy assignment

Figure 4: Transforming a one-sided conditional

graphs inherit many of the problems of the data dependence graph; for example, for constant propagation, we must still perform the program transformation shown in Figure 4. Moreover, they do not have a simple, local execution semantics [8].

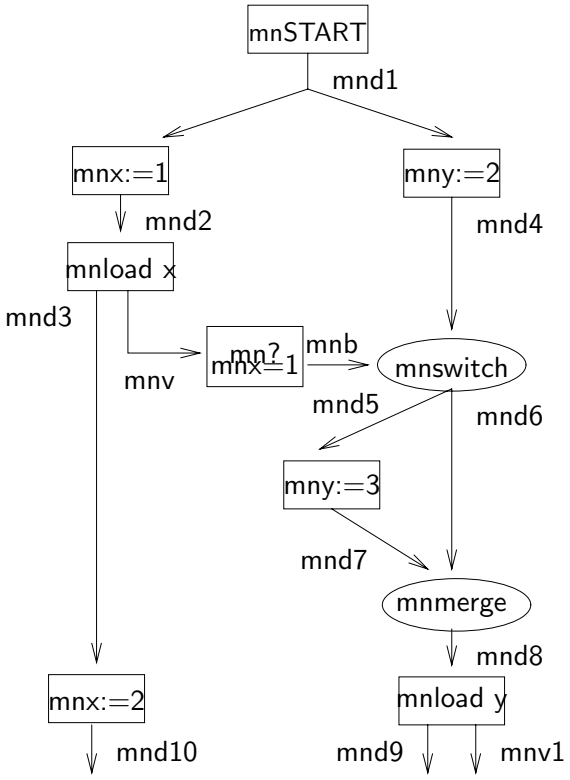
2.5 Summary

The control flow graph allows us to formulate a simple algorithm, based on abstract interpretation, that finds possible-paths constants without the need for program transformations. However, its asymptotic complexity is poor. Algorithms that use the various dependence graphs are more complex, and none of them find possible-paths constants without some program transformation. However, the asymptotic complexity of these algorithms is a factor of V better than the algorithm that use control flow graphs.

An ideal program representation for constant propagation would have a local execution semantics from which an abstract interpretation can be easily derived. It would also be a sparse representation of program dependencies, in order to yield an efficient algorithm. Like a Necker cube, this representation will permit two points of view — it can be viewed as a data structure that can be traversed efficiently for dependence information, but it can also be viewed as a precisely defined language with a local operational semantics. The dependence flow graph is just such a representation.

3 Dependence Flow Graphs

Figure 5 shows the dependence flow graph for the imperative language program considered in Figure 3. Dependence flow graphs are a synthesis of ideas from data dependence graphs and the dataflow model of computation. As in the data dependence graph, the dependence flow graph can be viewed as a data structure in which arcs represent dependencies between operations. It is easy to verify that for every dependence arc in the



```
var  x, y     : integer

     v, v1    : integer
        b     : boolean
d1, d4, d5    : output
d2, d4, d6    : flow
d7, d8, d10   : flow
d3, d9        : anti

   d1 =   START ()
   d2 =   store (x,1,d1)
  v,d3 =  load (x,d2)
    b =   equal (v,1)
   d4 =   store (y,2,d1)
 d5,d6 =  switch (b,d4)
   d7 =   store (y,3,d5)
   d8 =   merge (d7,d6)
 v1,d9 =  load (y,d8)
  d10 =   store (x,2,d3)
```

Figure 5: Dependence Flow Graph for a Small Program

data dependence graph (Figure 3), there is a corresponding path in the dependence flow graph (Figure 5). However, unlike data dependence graphs, dependence flow graphs are *executable*, and the execution semantics, called *dependence-driven execution*, is a generalization of the data-driven execution semantics of dataflow graphs. In dataflow graphs, nodes represent functional operators that communicate with each other by exchanging value-carrying tokens along arcs in the graph. These arcs can be viewed as flow dependencies since they connect a node producing a value, such as an integer or boolean, to nodes that consume this value; we will call such arcs *functional dependencies* in our presentation. In Figure 5, v, v1, and b are functional dependencies.

We extend the dataflow model by adding an imperative (updatable) global store and two operations called load and store which manipulate it. As one would expect, the load operator reads the contents of a storage location and outputs the value as a token. The store operator is the inverse of the load operator — it receives a value on a token and stores it into a memory location. To sequence these operations, we introduce a new kind of arc called an *imperative dependence*. For example, in Figure 5, d2 and d3 are imperative dependencies that sequence operations on location x, corresponding to arcs in the data

dependence graph. To preserve the local, token-pushing semantics of dataflow graphs, we make load and store operators produce a special token, $, when they have completed. These tokens flow down imperative dependence arcs to enable operators at the destinations of those arcs. For example, when the x := 1 operator executes, it produces a token carrying $ on line d2. This is said to *satisfy* the dependence d2, thereby *enabling* the load x operator for execution. When the load x operator executes, it produces tokens carrying $ on line d3 and the value 1 on line v. In this way, operations on a given memory location are sequenced, but operations on different locations can execute in parallel.

Imperative dependencies are further classified as *flow*, *anti* and *output* as in data dependence graphs. We classify d2 as a flow dependence and d3 as an anti-dependence. Note that dependence d4 is both a flow and an output dependence, since logically it corresponds to both of the dependence arcs coming out of the definition y := 2 in the data dependence graph. Dependence arcs that sequence operations on location y are intercepted by switch and merge operators, which implement flow of control as discussed below. These operators serve to combine control information with data dependencies, which is exactly what is missing from the representations discussed in Section 2.

To understand dependence flow graphs, it is useful to execute the graph depicted in Figure 5 by pushing tokens. Execution begins when the START operator sends a token carrying $ to the store operations x := 1 and y := 2. Depending on whether the token received on arc b is true or false, the switch operator outputs the token it receives on d4 onto either arc d5 or d6. In our example, the switch routes the token to d5, and the definition y := 3 is executed. The merge operator receives a token on either one (but not both) of its inputs, and simply outputs this token. The reader can verify that a token carrying the value 3 will be generated on arc v1.

In a forthcoming paper, we will describe how dependence flow graphs are constructed, starting from the control-flow graph of a program. This construction can handle unstructured control-flow. Some preliminary ideas are presented in an earlier paper [7]. From an analysis of the construction, we show two facts.

- Dependence flow graphs constructed by our algorithm satisfy Bernstein's conditions: that is, a store operator can never be enabled for execution simultaneously with another store or load operator on the same storage location.

- The dependence flow graph of a program whose control flow graph has E edges and V variables has size $O(EV)$.

Although token-pushing provides useful intuition, we adopt a different style of operational semantics in the formal development. Arcs in the dependence flow graph can be

viewed as names that represent a set of single assignment registers or temporaries. Producing a token carrying a value on an arc is similar to storing that value in the corresponding register. Explicit load and store operators to transfer values between the global store and a set of registers/temporaries have been used in the PL.8 compiler [5] and many Scheme compilers [19]. We develop this point of view in the rest of this section.

3.1 Acyclic Dependence Flow Graphs: Formal Semantics

From a formal perspective, a dependence flow graph is a set of *declarations* followed by a set of *definitions*. Declarations introduce names for locations in the store and for *dependencies*, which can be viewed as names for a set of single assignment registers or temporaries. The body of the dependence flow graph is a set of definitions. A definition is an equation with a left hand side consisting of one or more dependencies, and a right hand side consisting of the application of an operator to dependencies, locations, and constants. The operators and their arity are shown in the left column of Figures 6. A definition is said to be a *source* for dependencies named on the left hand side of the equation and a *sink* for dependencies named on the right hand side. A dependence has exactly one source but can have many sinks.

We now give a Plotkin-style, formal operational semantics for dependence flow graphs [17]. Rather than rewrite programs, as is common in this style of semantics, we will define a state transition semantics in which we rewrite *configurations*. Informally, a configuration represents the state of the computation and a transition represents a step in the computation. In our system, a configuration is a pair consisting of an *environment* and a *store*. To define them, we need the following sets.

- $V = Bool \cup Int \cup \{\$\}$ is the set over which we compute. The metavariables b and c stand for elements of V.
- Loc $= \{L_0, L_1, ...\}$ is an infinite set of global store locations. The metavariable x stands for an element of Loc.
- Dep $= \{d_0, d_1, ...\}$ is an infinite set of dependencies. The metavariables d, v, p, and t stand for elements of Dep.

The environment keeps track of the state of dependencies in the program and the store keeps track of the state of locations used by the program. The environment is a mapping from program dependencies to the set V. For technical reasons, a dependence will be added to the environment only when it is satisfied; therefore, the initial environment is empty.

Figure 6: Transition Rules for Acyclic DFGs

The environment grows monotonically during execution, in the sense that as computation progresses, dependencies are only added to and never deleted from the environment; in addition, the value bound to a functional dependence in the environment never changes. Similarly, the store is a mapping from the set of locations used in the program to the set V; however, locations can be updated arbitrarily. The store, like the environment, is initially empty and a location is added to the store the first time a value is stored to it.

Definition 1

1. *An* environment $\rho : D \rightarrow V$ *is a finite function — its domain* $D \subset Dep$ *is finite.*
2. *A dependence* d *is said to be* defined *or* satisfied *in* ρ *if* d *is in the domain of* ρ*. Otherwise, it is said to be* undefined *in* ρ*. The notation* $\rho[v \mapsto c]$ *represents an environment identical to* ρ *except for dependence* v *which is mapped to* c*.*
3. *A* store $\sigma : L \rightarrow V$ *is a finite function — its domain* $L \subset Loc$ *is finite. Just as for dependencies, we can talk about a location* x *being defined or undefined in a store* σ*.*

$t = \mathsf{loop}\ (t_{in}, t_{back})$:	$\dfrac{t_{in}.I \text{ defined} \quad \wedge \quad t.I.1 \text{ undefined}}{\langle \rho,\ \sigma \rangle \ \rightarrow\ \langle \rho[t.I.1 \mapsto \rho[t_{in}.I]],\ \sigma \rangle}$
$t = \mathsf{loop}\ (t_{in}, t_{back})$:	$\dfrac{t_{back}.I.j \text{ defined} \quad \wedge \quad t.I.j{+}1 \text{ undefined}}{\langle \rho,\ \sigma \rangle \ \rightarrow\ \langle \rho[t.I.j{+}1 \mapsto \rho[t_{back}.I.j]],\ \sigma \rangle}$
$t, t_{back} = \mathsf{until}\ (b, t_{in})$:	$\dfrac{\rho[b.I.j] = \mathit{false} \quad \wedge \quad t_{in}.I.j \text{ defined} \quad \wedge \quad t_{back}.I.j \text{ undefined}}{\langle \rho,\ \sigma \rangle \ \rightarrow\ \langle \rho[t_{back}.I.j \mapsto \rho[t_{in}.I.j]],\ \sigma \rangle}$
$t, t_{back} = \mathsf{until}\ (b, t_{in})$:	$\dfrac{\rho[b.I.j] = \mathit{true} \quad \wedge \quad t_{in}.I.j \text{ defined} \quad \wedge \quad t.I \text{ undefined}}{\langle \rho,\ \sigma \rangle \ \rightarrow\ \langle \rho[t.I \mapsto \rho[t_{in}.I.j]],\ \sigma \rangle}$

Figure 7: Transition Rules for Loop Operators

4. *A* configuration *is a pair* $\langle \rho,\ \sigma \rangle$ *consisting of an environment and a store. The initial configuration has empty environment and store.*

Figure 6 shows the transition rules for acyclic dependence flow graphs. The left column consists of definitions and the right column shows a precondition above the line and a transition below the line. If the definition in the left column is present in the dependence flow graph and the precondition on top of the line is satisfied, then the transition shown below the line can be performed.

As an example, consider a definition of the form $t = \mathsf{add}\ (t_1, t_2)$. We would expect this operator to execute when t_1 and t_2 are defined. Once this operator has executed, we want to disable this transition. Therefore, we perform the transition only if t is undefined. The load and store operators are the only operators that access the store. The load operator checks that the contents of location x are defined; this will catch an attempt to read from an uninitialized location. The switch and merge operators implement flow of control. Depending on the boolean value p, the switch operator satisfies either dependence t_T or t_F. The dependence at the output of the merge is satisfied when either of the dependencies at its input is satisfied. Notice that the rules check that at most one input dependence is satisfied.

3.2 Cyclic dependence flow graphs

As far as the input/output behavior of programs goes, loops can be replaced by tail-recursion. However, many loop optimizations, such as loop interchange, have no natural analog in the context of tail-recursion, so we felt it was important to model loops directly using cyclic dependence flow graphs. For this, we need two new operators called loop and

until which are used at loop entrance and loop exit respectively. In addition, the transition rules for the operators discussed in Section 3.1 must be altered slightly.

Consider the definition $t = \mathsf{add}\ (t_1, t_2)$ occurring inside a loop. t represents a different dependence in each iteration; to model this we index t by the iteration number, so that $t.i$ represents the dependence t in the i^{th} loop iteration.[6] $t.1$ is the dependence in the first iteration. This scheme extends naturally for nested loops so that for a two-dimensional loop, $t.i.j$ represents this dependence in iteration i of the outer loop and iteration j of the inner loop. It is sometimes convenient to write this as $t.I$ where I is a (two dimensional) *index vector* $i.j$. To reflect this intuition, the definition of environments is modified:

Definition 2 *Let Seq be the set of finite sequences of positive integers, including the empty sequence. An* environment $\rho : DS \rightarrow V$ *is a finite function — its domain* $DS \subset Dep \times Seq$ *is finite.*

To avoid introducing more notation, we will let the term dependence stand for both an identifier (arc) in the dependence flow graph and its dynamic instance in various iterations, relying on context to make the distinction clear. For any index vector I, the add operator can execute as soon as its operands are available, i.e. as soon as $t_1.I$ and $t_2.I$ are defined. Therefore, the rule for the add becomes:

$$t = \mathsf{add}\ (t_1, t_2): \qquad \frac{t_1.I, t_2.I \text{ defined} \quad \wedge \quad t.I \text{ undefined}}{\langle \rho,\ \sigma \rangle \rightarrow\ \langle \rho[t.I \mapsto (\rho[t_1.I] + \rho[t_2.I])],\ \sigma \rangle}$$

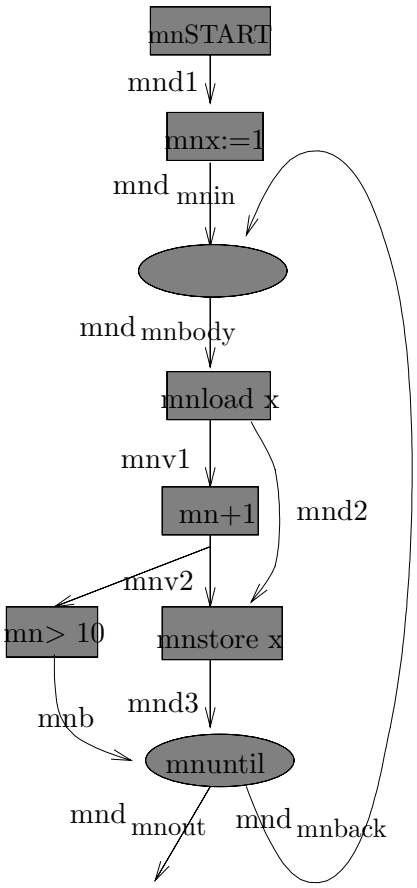
The transition rules for the other operators shown in Figure 6 are extended in a similar manner.

We now discuss the semantics of the loop and exit operators. Figure 8 shows a simple loop and its dependence flow graph. In the first iteration, the statement x := x+1 reads the value of x assigned by the statement x := 1 outside the loop. Therefore, in the dependence flow graph, we must have a dependence from the assignment statement outside the loop to the use within the loop. In subsequent iterations, the statement x := x+1 reads the value of x assigned in the previous iteration. Therefore, in the dependence flow graph, we must have a dependence from the assignment to x in the i^{th} iteration to the use of x in the $(i+1)^{th}$ iteration. The loop operator (see Figure 7) accomplishes this transfer of dependence from outside the loop into the first iteration and from one iteration to the next. The until operator determines if another iteration of the loop should be executed. In the definition $t, t_{back} = \mathsf{until}\ (p, t_{in})$, if p is false then another iteration is to be performed,

[6] This device is like scalar expansion [15].

```
x := 1;
loop
        x := x+1
until (x > 10)
```

(a) Source Program



(b) Dependence Flow Graph

Figure 8: Dependence Flow Graph of a Simple Loop

and the dependence t_{back} is satisfied. Otherwise, the loop is to be exited; if this is the $I.j$ iteration of the loop, the dependence $t.I$ outside the loop is satisfied.

3.3 Discussion

The transition system for dependence flow graphs, as described above is deterministic in the sense that it has the *one-step Church-Rosser property*. The proof, which we have omitted for lack of space, rests on the fact that dependence flow graphs, by construction, satisfy Bernstein's conditions. We refer the interested reader to a companion technical report [16].

We can exploit the one-step Church-Rosser property to define a simple interpreter for dependence flow graphs. The interpreter maintains an environment and a store, and keeps a worklist of definitions that may be ready for execution. The initial environment and store

are empty, and the worklist is initialized to {START}. While the worklist is not empty, the interpreter dequeues a definition, checks the precondition and performs the transition if the precondition is satisfied. All definitions that are sinks for dependencies sourced by the definition just executed are then enqueued onto the worklist.

The major difference between our representation and conventional dependence graphs is that dependencies, for us, are part of the computational model, and are manipulated by an algebra of operators. Note that load and store, switch and merge, and loop and until are, in an algebraic sense, inverses of each other. Data dependencies are combined with control, and in the next section, we demonstrate how this facilitates the development of optimization algorithms.

4 Constant Propagation on Dependence Flow Graphs

In this section, we demonstrate how global constant propagation can be performed on dependence flow graphs using a simple algorithm based on abstract interpretation. We show that for any program, we can write down a set of equations whose solution corresponds to the possible-paths constants for that program. Next, we show that this solution can be computed efficiently, thereby developing an algorithm that has the same asymptotic complexity as the algorithm due to Wegman and Zadeck [20]. This algorithm can be proved correct by an induction on the length of the computation.

4.1 Equational Characterization of Constants

Figure 9 shows how to write down a set of semantic equations from a dependence flow graph representation of a program. The equations are obtained by replacing the operator in each definition with a function that denotes the abstract interpretation of the operator in *Lat*. We let *DenOp* stand for the interpretation of an arithmetic or logical operator op in the domain *Lat*, as in Section s:constants. The function *DenSw* stands for the interpretation of switch and is defined as follows:

$$DenSw(b,c) = \begin{cases} c, c & \text{if } b = \top \\ c, \bot & \text{if } b = \mathsf{true} \\ \bot, c & \text{if } b = \mathsf{false} \\ \bot, \bot & \text{if } b = \bot \end{cases}$$

This is similar to the standard interpretation of switch, except that it deals with the case when b is $\top$ — if the value of the predicate cannot be determined during constant propagation, then the input value c is propagated to both sides of the switch. Therefore, in

Syntactic Equation		Semantic Equation	
d	$=$ START $()$	d	$= \$$
v	$=$ op (v_1, v_2)	v	$= DenOp(v_1, v_2)$
v_t, v_f	$=$ switch (b, v)	v_t, v_f	$= DenSw(b, v)$
v	$=$ merge (v_1, v_2)	v	$= v_1 \sqcup v_2$
v, d	$=$ load (x, d_{in})	v, d	$= d_{in}, d_{in}$
d	$=$ store (x, v, d_{in})	d	$=$ if $d_{in} = \perp$ then $\perp$ else v
v	$=$ loop (v_{in}, v_{back})	v	$= v_{in} \sqcup v_{back}$
v, v_{back}	$=$ until (b, v_{in})	v, v_{back}	$= v_{in}, v_{in}$

Figure 9: Abstract Interpretation of Operators

the abstract interpretation, both inputs of a merge can be defined. The output of a merge operator is constant only if both inputs are the same constant or if one side of the merge is never executed, and the other side is constant. In the equations, this is stated compactly using the least upper bound operator on Lat.

In the standard semantics, the global store was used to communicate values between the load and store operators. As is the case in all the algorithms discussed in Section 2, the global store plays no role in our constant propagation algorithm. Instead, we take advantage of the fact that there is a flow dependence path in the graph from a store to every load dependent on it. Lattice values are propagated along these paths. The store operator propagates the value of its input to its output, provided that d_{in} is not $\perp$ — that is, if it is possible that this operator may be executed. Therefore, the load operator need only propagate the value of input d_{in} to its outputs.

For any dependence flow graph, we can write down a set of semantic equations over Lat in which the functions on the right hand side are monotonic and continuous. It is a well-known result that such a system of equations has a least solution. Figure 10 shows these values for the program of Figure 5. The possible-paths constants can be read off from the least solution of the semantic equations as follows. Let $\mathcal{C} : D \rightarrow Lat$ be the least solution. If t is a functional dependence, then, as in Section 2, $\mathcal{C}[t] = \perp$ means that the operator that defines t will never be executed, $\mathcal{C}[t] = c$ means that if t is ever assigned a value, it is assigned the value c, and $\mathcal{C}[t] = \top$ means that the value of t cannot be determined to be constant. The values assigned to imperative dependencies must be interpreted a little differently. Consider dependence d2 in Figure 10. This dependence is given the value 1 by the constant propagation algorithm, but it is given the value \$ in the standard interpretation which uses the global store, rather than dependencies, to transmit

Figure 10: Result of Constant Propagation in Figure 5

values between a store operation and corresponding load operations. If t is an imperative dependence, then $\mathcal{C}[t] = \perp$ means that the operator that defines t will never be executed, but if $\mathcal{C}$[t] is any other value, we conclude that this operator may be executed — that is, t may get the value $ in the standard interpretation.

To compute the least solution of the equations efficiently, we run the dependence flow graph interpreter defined in Section 3.3, using the abstract, rather than the standard, interpretation of the operators. This abstract interpreter maintains only an environment, since the store plays no role in constant propagation. In this environment, we keep only a single value associated with each dependence, rather than an indexed family of values, because a dependence is constant only if it is constant in all iterations. Since there are only a finite number of dependencies, we start with an initial environment that maps all dependencies to $\perp$. The worklist of definitions ready for processing is initialized to {START}. While the worklist is non-empty, we remove a definition from the worklist and update the environment using the abstract interpretation rules shown in Figure 9. This update to the environment consists of binding new values to the dependencies whose source is the definition being interpreted.

If the value bound to a dependence changes, we add every definition that is a sink for that dependence to the worklist. Since there can be $O(EV)$ edges in the dependence flow graph and the value propagated along each edge can change at most twice, the complexity of this constant propagation algorithm on dependence flow graphs is $O(EV)$. This is the same asymptotic complexity as that of the algorithm due to Wegman and Zadeck.

This algorithm can be proved correct by a simple induction on the length of the execution sequence. We omit the proof for lack of space and refer the interested reader to the technical report [16].

5 Conclusions

The ideas presented in this paper form the basis of the Typhoon parallelizing compiler project at Cornell University. We have implemented prototype front-ends that translate programs in FORTRAN and in the dataflow language Id into an intermediate language called Pidgin. Pidgin is a textual form of the dependence flow graph data structure, on which our optimizer is built. The optimizing portion of the compiler is a source-to-source

transformer of Pidgin programs.

Much of our future work will focus on loop transformations, scheduling, and code generation for specific architectures. We have extended the definition of dependence flow graphs so that we can represent the dependence information needed to implement loop transformations. Preliminary work on the scheduling of dependence flow graphs has focused on generating code for pipelined RISC architectures such as SPARC; future work will target dataflow architectures, NUMA machines, and VLIW architectures.
